## AGRADECIMENTOS

Aos meus pais, João Batista Santos e Romilda Maria Ferreira Santos agradeço os exemplos de honestidade, compromisso com seus objetivos e confiança, fatores indispensáveis para uma sólida formação humana e profissional. Agradeço ainda as colaborações diretas na execução do presente trabalho.

A minha querida Fernanda dos Santos Farnese, agradeço o companheirismo, amor, apoio e cumplicidade.

Ao grande Jorge Abdala Dergam, “capitão do Beagle”, meus sinceros agradecimentos pela oportunidade de tornar-me um “marujo”, pela confiança, orientações, amizade e apoio na execução do presente trabalho.

Ao Tiago Leão Pereira agradeço o suporte nos trabalhos de bancada.

Aos companheiros de laboratório meu obrigado pela troca de experiências e amizade ao longo desses dois anos de trabalho.

Ao Uedson Jacobina e Walter Evangelista agradeço a gentileza em fornecerem amostras de tecidos utilizadas nesse estudo.

Aos pescadores José Tiago da Costa, Sr. Raul de F. Guimarães e Anderson M. R. de Souza obrigado pela participação fundamental na realização deste trabalho, uma vez, que sem traíras, não existe filogeografia de traíras!

Agradeço ao professor Luiz Antônio Carlos Bertollo pelas considerações ao trabalho e ao Marcelo Belo Cioffi pelo auxílio na execução das hibridações cromossômicas.

Aos amigos de república Leonardo Araújo, Márcio Gomes, José Luiz de Alcantra Filho e Eduardo Guatimosim obrigado pela troca de experiências e ótima convivência ao longo desses dois anos.

Ao CNPq, obrigado pela concessão da bolsa de mestrado.

Ao programa de Pós-Graduação em Genética e Melhoramento da UFV agradeço a oportunidade de cursar o mestrado.

À Universidade do Estado de Minas Gerais campus da Fundação Educacional Divinópolis agradeço o financiamento para a coleta de material e início da execução do presente trabalho.

Por fim, meus sinceros agradecimentos àqueles que por mero esquecimento não foram aqui lembrados, mas contribuíram significativamente para a execução do presente trabalho. Obrigado!

## BIOGRAFIA

Udson Santos, filho de João Batista Santos e Romilda Maria Ferreira Santos, nasceu dia 22 de janeiro de 1986, em Divinópolis-MG.

Residente em Divinópolis cursou o ensino de primeira à quinta série na Escola Estadual Rosa Vaz de Araújo. Na escola municipal Centro Técnico Pedagógico (CETEP) concluiu o ensino fundamental em dezembro do ano de 2000. Em dezembro de 2003 concluiu o ensino médio na Escola Estadual Joaquim Nabuco.

Em fevereiro de 2004 iniciou a graduação em Ciências Biológicas na Universidade do Estado de Minas Gerais, campus da Fundação Educacional de Divinópolis, concluindo-o em dezembro de 2007.

Em março de 2008 ingressou no mestrado no Programa de Pós-Graduação em Genética e Melhoramento da Universidade Federal de Viçosa (UFV), concentrando seus estudos em citogenética e filogeografia em populações de traíras *Hoplias malabaricus*. Em novembro de 2009 foi aprovado para cursar o doutorado em Genética e Melhoramento na mesma instituição, com inicio em março de 2010.

## RESUMO

SANTOS, Udsom, M.Sc., Universidade Federal de Viçosa, fevereiro de 2010.

**Filogeografia citogenética e molecular em populações de traíras**

***Hoplias malabaricus* (Bloch, 1794), do leste do Brasil.** Orientador:

Jorge Abdala Dergam dos Santos. Co-Orientadores: Karla Suemy Clemente Yotoko e Rubens Pazza.

A fauna de peixes dulcícolas neotropicais é considerada a mais rica do mundo. Toda essa diversidade é resultante da complexa história paleohidrológica dos rios sul e centro-americanos, a qual promoveu vicariância e dispersão da biota aquática ao longo de milhões de anos. A traíra *Hoplias malabaricus* é um caracídeo com ampla distribuição neotropical, hábito sedentário e comportamento predatório. Graças à sua rusticidade e abundância nos neotrópicos, a traíra é amplamente estudada, representando um importante modelo biológico experimental. As populações de *H. malabaricus* são caracterizadas por apresentarem sete distintos cariomorfos, listados de A-G. A distribuição simpátrica e alopátrica desses cariomorfos tem sido considerada como evidência da existência de múltiplas linhagens que comportam-se como boas espécies, dentro do mesmo táxon nominal. Para testar essa hipótese, foram analizados os padrões biogeográficos, citogenéticos e moleculares (DNA mitocondrial) de 17 populações (73 espécimes) coletadas em 12 bacias do nordeste e sudeste do Brasil. Os padrões citogenéticos indicaram a existência de um sistema de cromossomos sexuais XX/XY no cariomorfo  $2n=40F$ . Os dados moleculares indicaram ausência de fluxo gênico entre cariomorfos com  $2n=40$  e  $2n=42$  e constituem a primeira evidência da origem costeira das populações do rio Jacaré. A aparente ausência de uma taxa de evolução molecular constante não permitiu correlacionar eventos geomorfológicos de dispersão no passado e foi interpretada como resultante das extremas flutuações demográficas ao longo da evolução desse complexo de espécies. Os resultados apresentados indicam que a identificação cariotípica representa informação relevante e imprescindível para a inclusão dos dados experimentais num contexto filogenético.

## ABSTRACT

SANTOS, Udson, M.Sc., Universidade Federal de Viçosa, February, 2010.  
**Molecular and karyotypic phylogeography in populations of the traíras *Hoplitas malabaricus* (Bloch, 1794), in Eastern Brazil.** Adviser: Jorge Abdala Dergam. Co-advisers: Karla Suemy Clemente Yotoko and Rubens Pazza.

The Neotropical freshwater fish fauna is considered the richest of the world. This diversity is the direct result of the complex palaeohydrological history of the Central and South-American rivers, a process that promoted vicariance and dispersion of the aquatic biota along millions of years. The common trahira *H. malabaricus* is a widespread, sedentary predatory Neotropical characin. Due to its abundance and tolerance to transportation and laboratory conditions, the trahira has become a relevant model organism for experimental biology. *H. malabaricus* populations are characterized by 7 karyomorphs named A-G. The allopatric and sympatric distribution of these karyomorphs has been considered as evidence for the existence of multiple lineages that behave as good species within this nominal taxon. To test this hypothesis, biogeographic, cytogenetic and molecular (mitochondrial DNA) patterns were analyzed in 17 populations (73 specimens) from 12 basins in northeastern and southeastern Brazil. Cytogenetic patterns indicated a XX/XY chromosome system in karyomorph 2n=40F. Molecular data indicated absence of gene flow among karyomorphs 2n=40 and 2n=42 and provided the first evidence of a coastal origin of the 2n=42 karyomorphs in the Jacaré River. The absence of a constant molecular rate of substitution hampered a correlation of past dispersal events and it was interpreted as an effect of extreme demographic fluctuations in this species complex. These results indicate that karyotypic identification is relevant and necessary for placing all experimental data in a phylogenetic context.

## **1. OBJETIVOS**

### **1.1 OBJETIVOS GERAIS**

Realizar análises filogeográficas com marcadores citogenéticos e moleculares em populações de traíras *Hoplias malabaricus* de 12 bacias do leste do Brasil.

### **1.2 OBJETIVOS ESPECÍFICOS**

- Cariotipar *Hoplias malabaricus* ocorrentes nos rios Pará, Pandeiros, Jacaré e córrego Tombadouro;
- Avaliar a existência de diferenças intra e interpopulacionais quanto a variabilidade cariotípica, Ag-NORs, regiões heterocromáticas, seqüências de DNA satélite 5SHindIII, 5S rDNA, 18S rDNA, regiões ricas em GC e regiões ricas em AT em *H. malabaricus* ocorrentes nos rios Pará, Pandeiros, Jacaré e córrego Tombadouro;
- Gerar hipóteses filogeográficas considerando o fragmento de DNA mitocondrial ATPAse 6 e informações citogenéticas obtidas em populações de *H. malabaricus* das bacias:
  - ✓ do rio São Francisco: rios Pará (calha e córrego Tombadouro), Pandeiros, Curvelo (rio das Velhas), e na localidade de Ibimirim (baixo São Francisco),
  - ✓ do rio Grande (rio Jacaré) e
  - ✓ bacias costeiras: rios Itapicuru, Paraíba do Sul, Itabapoana, Macaé, São João, Ribeira, cachoeiras de Macacu, Baia de Paranaguá; e na bacia do rio Doce (lagoas Dom Helvécio e Carioca).

## 2. INTRODUCTION

The Neotropical region harbours 6025 species of freshwater fishes (Reis *et al.*, 2003), but perhaps as many as 8000 (Schaefer, 1998), the result of a long evolutionary history of isolation and specialization, involving mainly Otophysan fishes. Freshwater fishes are highly suitable for the recovery of past biogeographic processes, due to their obligatory relationship with water (Myers, 1938). The biogeographical information relevant for fish diversification has been reviewed by Lundberg *et al.* (1998) and Ribeiro (2006). The former revision focused on the evolution of Andean geomorphology and the effects of this process on the South American continent, whereas the latter work dealt with the evolution of particular coastal drainages, their geomorphological interactions with continental basins and the expected levels of phylogenetic divergence among fishes derived during this complex temporal scenario.

Among Neotropical freshwater fishes, the trahira, *Hoplias malabaricus* (Bloch, 1794), has one of the largest distributional ranges, occurring from Panamá to the Buenos Aires Province in Argentina (Berra, 2007). *Hoplias malabaricus* is well adapted to life in small, isolated populations, in conditions that may facilitate the stochastic fixation of chromosomal rearrangements (Sites & Moritz, 1987). This species is one of the cytogenetically most studied taxa and shows a conspicuous karyotypic diversification, with up to seven karyomorphs with diploid numbers ranging from 39 to 42. Three groups of karyomorphs are readily evident, based on distribution ranges. Two karyomorphs,  $2n=42A$  and  $2n=40C$ , are the most widespread and occur in sympatry in the Lower Paraná-Paraguay and Amazon basins. A second, less widely spread group is represented by three karyomorphs:

- $2n=40F$  occurs in the São Francisco Basin, in the lower portions of the Tocantins River, in coastal drainages in Suriname, and in minor basins in north-eastern Brazil;
- $2n=39/40D$  occurs in the Upper Paraná (in sympatry with  $2n=42A$ ) and;

- $2n=40/41G$  occurs exclusively in the Amazonian Basin in the Aripuanã, Madeira and Trombetas rivers.

The third group consists of karyomorphs with much restricted distributions. For example,  $2n=42B$  occurs in the Doce Basin (also in sympatry with  $2n=42A$ ), and  $2n=42E$  occurs only in the Trombetas River, as indicated by surveys conducted so far (Bertollo *et al.*, 2000).

The lack of hybrids between sympatric karyomorphs has been interpreted as evidence for the existence of several distinct species within this nominal taxon (Bertollo *et al.*, 1986; Bertollo *et al.*, 2000). Therefore, uniparental molecular markers can be a particularly useful complement to assess gene flow in wild populations. To date, molecular studies on *H. malabaricus* have been restricted to populations in the Doce Basin (Dergam *et al.*, 2002) and the Iguaçu Basin (Dergam *et al.*, 1998). Both studies indicated phylogenetically related populations in the coastal and continental basins, but failed to reveal the direction of dispersal events.

Karyotypic and molecular patterns of variation may reveal vicariances and dispersals that provide insights into evolutionary processes that may involve other components of the aquatic fauna. The congruence of independent molecular and cytogenetic characters may give support to the hypothesis that at least some karyomorphs behave as valid species within *H. malabaricus*. A better understanding of *H. malabaricus* species-level systematics is needed to correctly interpret the comparative physiological, behavioural and anatomical studies in an explicit phylogenetic framework (Harvey & Pagel, 1991). Biodiversity patterns in this species complex also bear potential information to understand the palaeohydrology of the continent. In the present study, patterns of cytogenetic and molecular variation of *H. malabaricus* populations in the São Francisco, Grande and in several coastal basins along Eastern Brazil were analyzed using molecular and cytogenetic techniques.

### **3. MATERIALS AND METHODS**

### 3.1 SPECIMENS AND CHROMOSOME PREPARATION

Cytogenetic analyses were carried out on 49 specimens collected in the Pandeiros River, Pará River and its headwaters in the Tombadouro Creek and in the Jacaré River. (Table I, Fig. 1). Cell division was stimulated *in vivo* with two daily applications of Munolan®, a commercially available antigen lysate, following Molina (2001). Mitotic chromosomes were obtained from cell suspensions of the anterior kidney, using the conventional air-drying method (Bertollo *et al.*, 1978). Fish were previously anesthetized with clove oil according to Henyey *et al.* (2002). Secondary data from 10 populations with known chromosome numbers were also included in the analysis.

### 3.2 CHROMOSOME STAINING

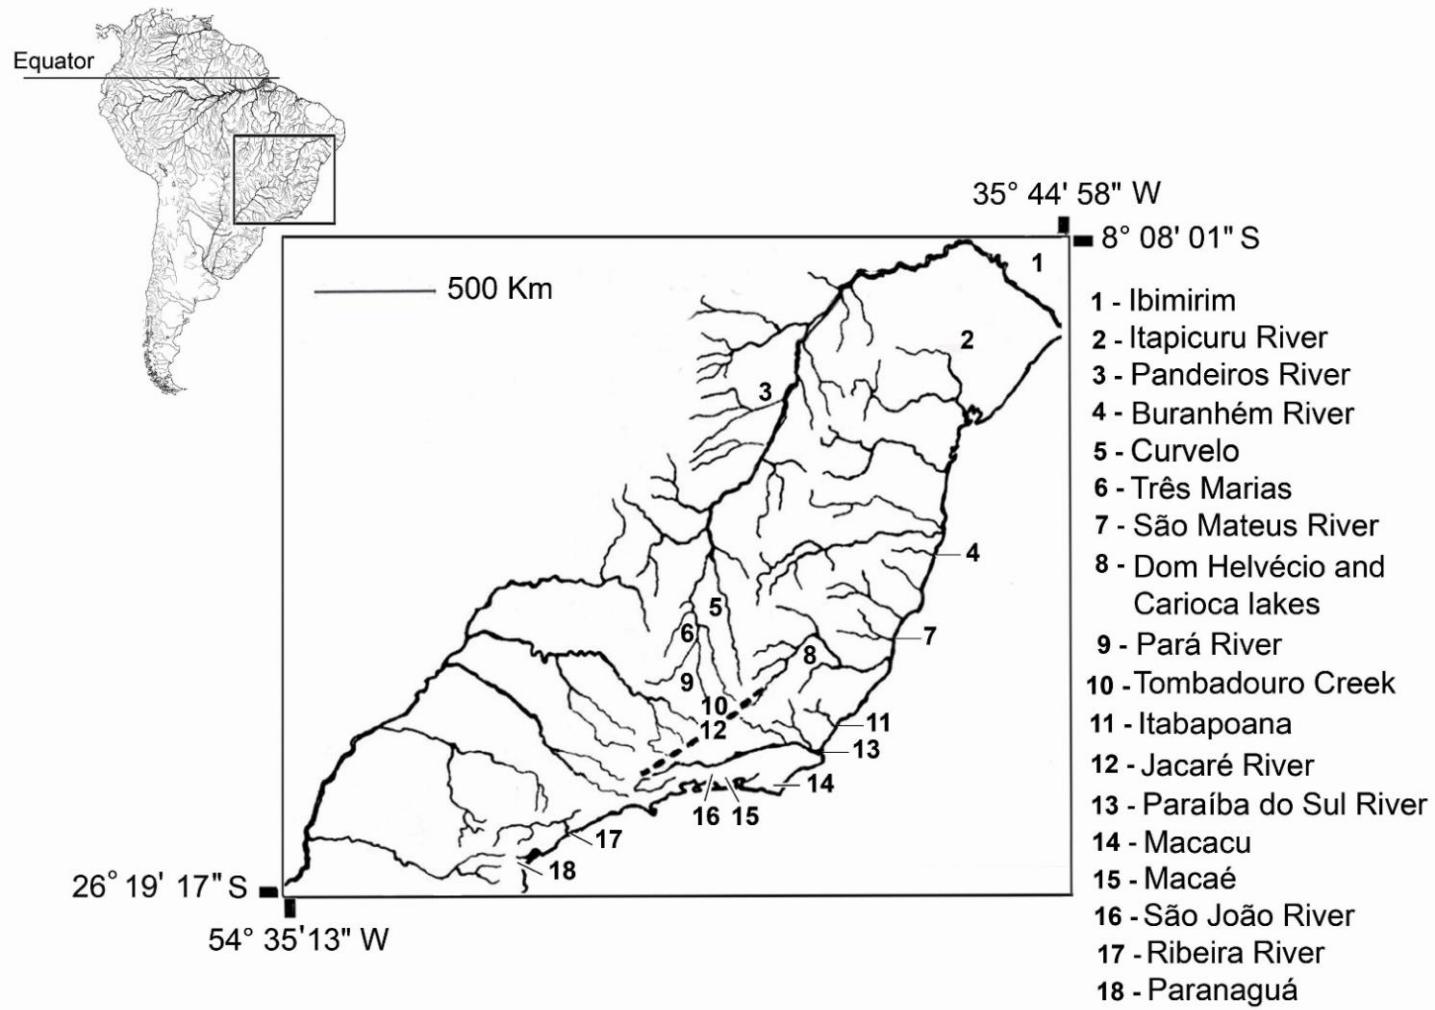

In addition to the standard Giemsa method, chromosomes were analyzed using silver nitrate staining (Howell & Black, 1980) to visualize the nucleolar organizing regions (Ag-NORs). C banding was also employed to detect C-positive heterochromatin (Sumner, 1972). DAPI and Chromomycin A3 (CMA3) fluorescence staining were used to identify the chromosome AT and GC rich regions, respectively (Sola *et al.*, 1992). Some populations with unknown karyotypes (or whose karyotypes are being studied by JAD) were also included in this study (see below).

### 3.3 CHROMOSOME HYBRIDIZATION AND KARYOTYPIC ANALYSIS

Fluorescent *in situ* hybridization (FISH) was performed according to Pinkel *et al.* (1986) using three repetitive DNA sequences probes isolated from the genome of *H. malabaricus*. The first probe contained a 5S rDNA repeat copy and included 120 base pairs (bp) of the 5S rRNA encoding gene and 200 bp of the non-transcribed spacer (NTS) (Martins *et al.*, 2006). The second probe is specific to *H. malabaricus* (Ferreira *et al.*, 2007) and contained a copy of the repetitive satellite 5SHindIII-DNA sequence with 360 bp composed of a 95-bp segment similar to the 5S rRNA gene of the first

and a 265-bp segment similar to the NTS of the first probe (Martins *et al.*, 2006). The third probe corresponded to a 1400 bp-segment of the 18S rRNA gene obtained by the polymerase chain reaction (PCR) from nuclear DNA (Cioffi *et al.*, 2009). The probes were labelled by nick-translation with biotin-14-dATP (Bionick Labeling System-Invitrogen). Signal detection and its amplification were performed using conjugated avidin-FITC and anti-avidin-biotin (Sigma). The chromosomes were counterstained with propidium iodide (50 µg mL<sup>-1</sup>) and analyzed with an Olympus BX50 epifluorescence microscope. The chromosomal images were captured using CoolSNAP-Pro software (Media Cybernetics). About 30 metaphase spreads were analyzed per specimen to determine the diploid chromosome number and karyotypic structure. Chromosomes were classified as metacentrics (m) or submetacentrics (sm), according to centromeric index values proposed by Levan *et al.* (1964).

### 3.4 DNA EXTRACTION AND MOLECULAR ANALYSIS

DNA extraction followed Boyce *et al.* (1989). Fragments of ATPase 6 were amplified using primers L8524 (5'-AAY CCT GAR ACT GAC CAT G- 3') and H9236 (5'-GTT AGT GGT CAK GGG CTT GGR TC- 3') (Quenouille *et al.*, 2004). Double stranded DNA was synthesized in 50 µL reactions containing 10 µL dNTPs (1 mM), 5 µL reaction buffer (200 mM Tris-HCl pH 8.4, 500 µM KCl), 2 µL MgCl<sub>2</sub> (50 mM), 2 µL of each primer (10 mM), 0.5 µL (2.5 U) of Taq DNA polymerase (Phoneutria), 2 µL of template DNA (100 ng/µL) and 26.5 µL of H<sub>2</sub>O. PCR conditions were as follows: 94° C (2 min), 5 cycles of 94° C (45 s), 54° C (45 s), 72° C (1.5 min), 29 cycles of 94° C (45 s), 58° C (45 s), 72° C (1.5 min). PCR products were purified using Qiaquick (Qiagen): 5 µL of the purified PCR product were used in a 10 µL cycle sequencing reaction using a dRhodamine terminator cycle sequencing kit (PE Applied Biosystems). Sequences were aligned using CLUSTAL W 1.83 in MEGA 4.0 (Tamura *et al.*, 2007). Phylogenetic trees were constructed with neighbour joining (NJ) (Saitou & Nei, 1987), maximum parsimony (MP), maximum likelihood (ML) (Felsenstein, 1981) and Bayesian inference (MB) (Huelsenbeck & Ronquist, 2001). The model of molecular evolution that best

fitted the data was chosen using Modeltest 3.7 (Posada & Crandall, 1998), and haplotype divergence was estimated within and between haplogroups using this selected model. Phylogenetic signal in NJ, MP and ML trees was assessed using bootstraps with 1000 repetitions. Bayesian inference was performed with 5 million MCMC steps to produce posterior probabilities of nodes in the tree with Mr Bayes. *Hoplias lacerdae* Miranda Ribeiro, 1908 was used as an outgroup. Sequences were deposited in GenBank (accession numbers GQ848606–GQ848642).

## 4. RESULTS

### 4.1 KARYOTYPIC DATA

#### *Karyomorph 2n=40F*

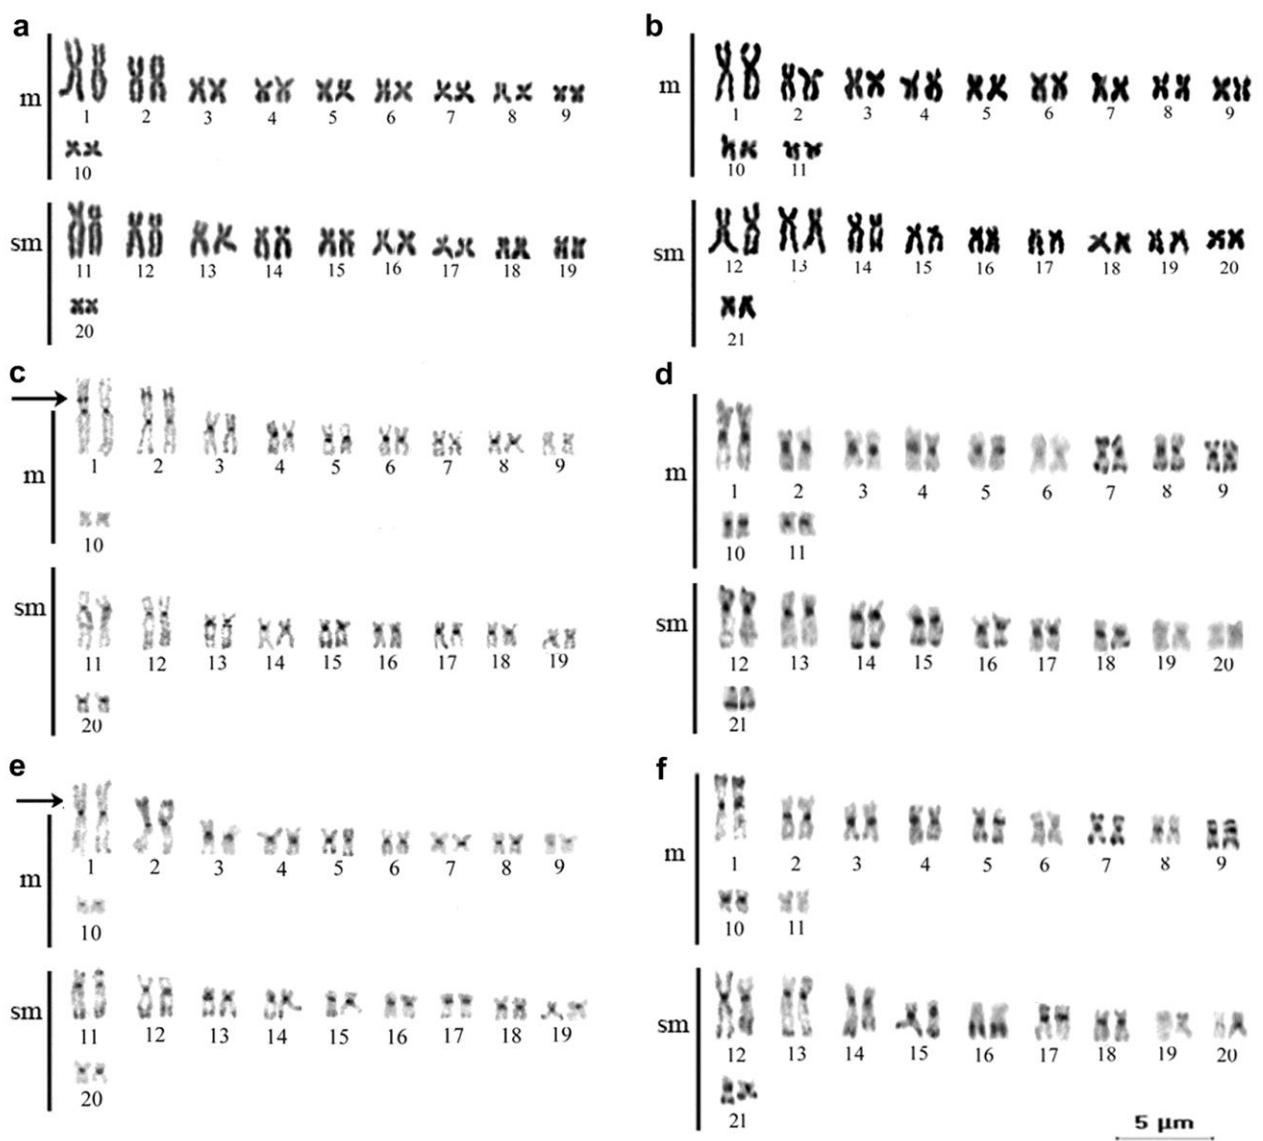

All specimens from the Pandeiros and Pará rivers (except those from Pará's headwaters, in Tombadouro Creek) had  $2n=40$  chromosomes for both sexes. The karyotypes were composed of 10 m + 10 sm pairs, without morphologically differentiated sex chromosomes using Giemsa conventional staining (Fig. 2a), and were typical  $2n=40F$  karyomorphs. C-banding showed heterochromatic blocks in centromeric regions, except for chromosome pairs Nos. 9 and 10, which had less conspicuous blocks, in addition to faint telomeric marks in some chromosome pairs. Males always showed an interstitial heterochromatic block in the short arms of one homologue of the first chromosome pair (Fig. 2c), whereas females lacked this block (Fig. 2e). This heterochromatic region was negative for DAPI staining but failed to show fluorescence with CMA3. A proximal heterochromatic block located on the short arms of a small submetacentric pair was the only observed GC-rich segment in both populations (Fig. 3f, i). Ag-NORs were telomeric, and their numbers were either fixed (four in the Pará River) or varied from 4 to 5 (Pandeiros River) (Fig. 4a, b). FISH analyses with the repetitive sequences showed no differences between these two populations. The 18S rDNA probe hybridized on the pericentromeric region of one metacentric pair and on the telomeric regions of two submetacentric pairs (Fig. 3a). The 5S rDNA probe hybridized on the pericentromeric region of a medium-sized metacentric pair

(Fig. 3c). The repetitive 5*S**Hind*III-DNA was mapped in the centromeric region of 10 chromosome pairs (Fig. 5a). Although Ibimirim samples were not karyotyped, they were collected in a region with populations characterized by 2n=40F karyomorph and were assumed to share this karyomorph.

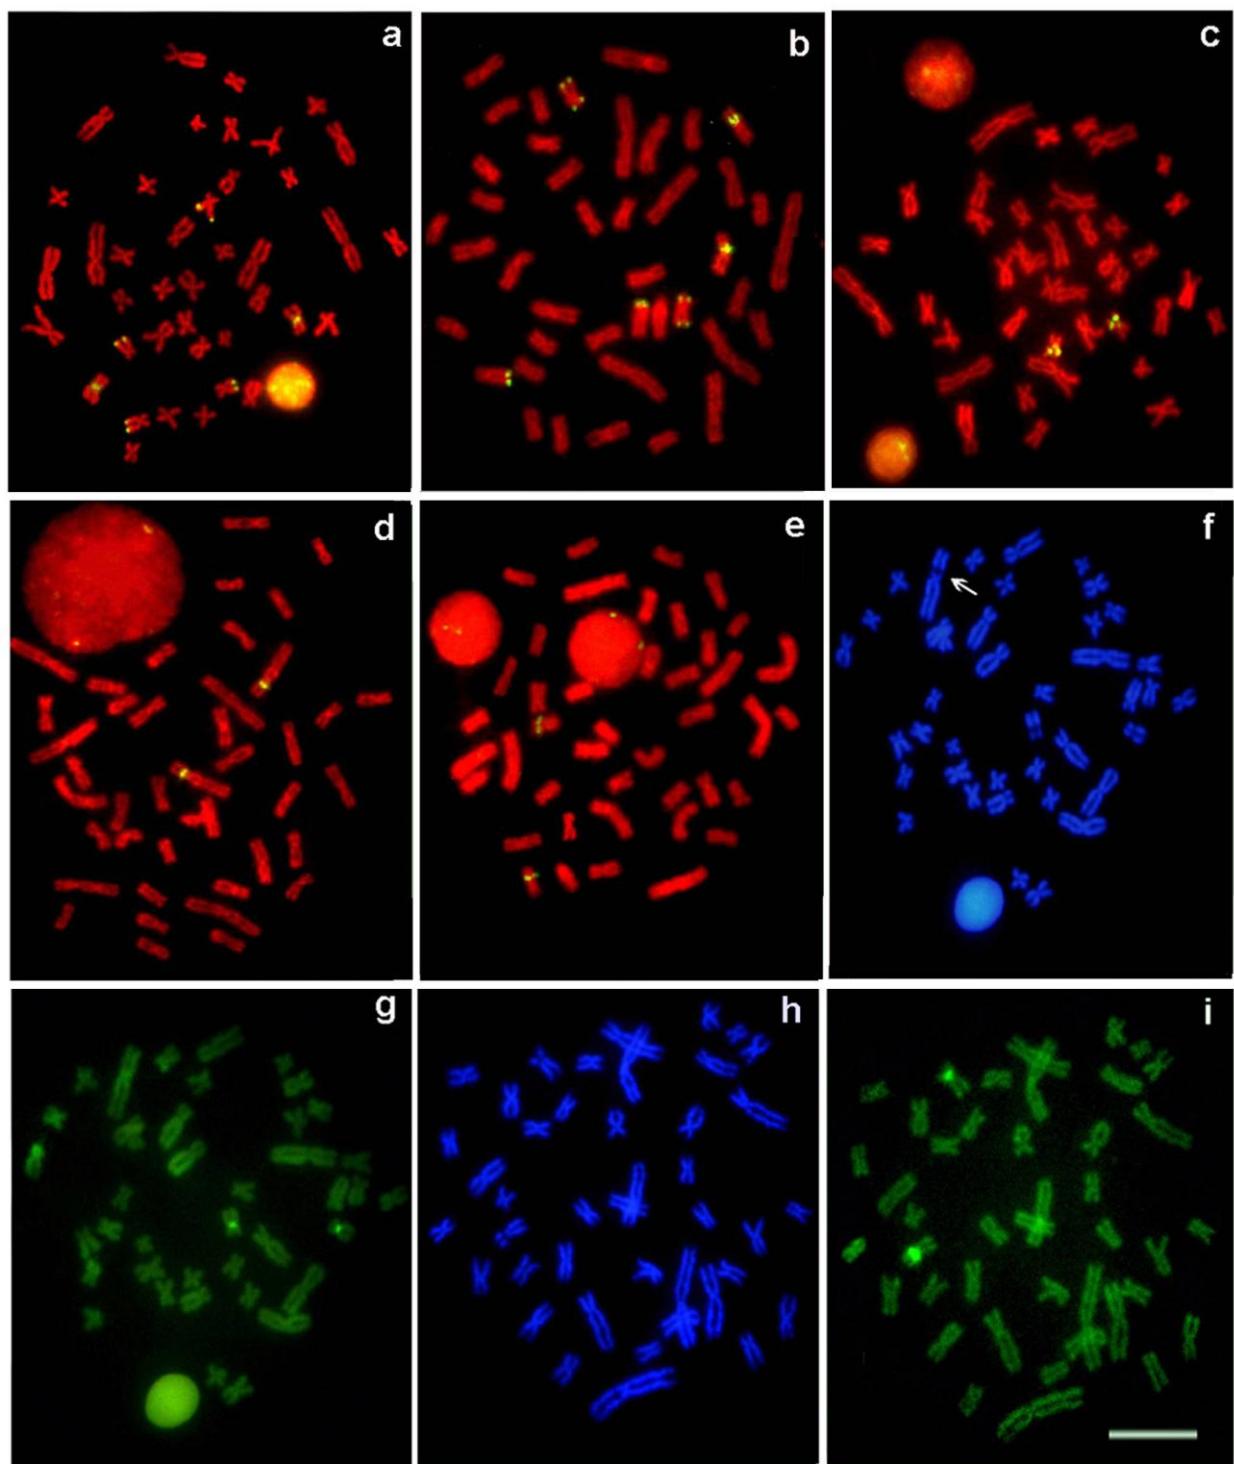

#### *Karyomorph 2n=42A*

In the headwaters of Tombadouro Creek, all specimens had 2n=42 chromosomes, with a karyotype consisting of 11 m + 10 sm pairs, without morphologically differentiated sex chromosomes (Fig. 2b), and were considered to be typical 2n=42A karyomorphs. Besides some telomeric marks, conspicuous heterochromatic bands were found in the centromeric region of all chromosomes, except for chromosome pairs No. 6, 19 and 20, which showed faint blocks (Fig. 2d). Ag-NORs varied among and within individuals (1–2 pairs), and bitelomeric NORs were evident in either 1 or 2 chromosomes (Fig. 4c). In this population, the 18S rDNA probe hybridized on three chromosome pairs, with interstitial, telomeric and bi-telomeric sites (Fig. 3b). The 5S rDNA probe hybridized on the interstitial region of a large submetacentric pair (Fig. 3d). The repetitive 5*S**Hind*III-DNA probe bound to the centromeric region of nine chromosome pairs (Fig. 5b).

Specimens from the Jacaré River in the Grande drainage, had 2n=42 karyomorphs composed of 11 m + 10 sm pairs, without morphologically differentiated sex chromosomes (Fig. 2b) and represented a typical 2n=42A karyomorph. Heterochromatic blocks were centromeric in most chromosomes, except for pairs No. 6, 8, 11, 19 and 20, which showed faint bands, in addition to telomeric marks in some chromosome pairs (Fig. 2f). Ag-NORs were restricted to telomeric regions of two chromosomes (Fig. 4d). Fluorescent regions hybridized with 18S rDNA and 5*S**Hind*III-DNA and showed a pattern similar to the Tombadouro Creek sample. Additionally, the 5S rDNA probe hybridized on the interstitial region of a small metacentric pair (Fig. 3e). As was the case with the Ibimirim samples, Paranaguá and Macacu samples were collected within the range of 2n=42A populations (JAD unpublished data) and were therefore assumed to be derived from these populations.

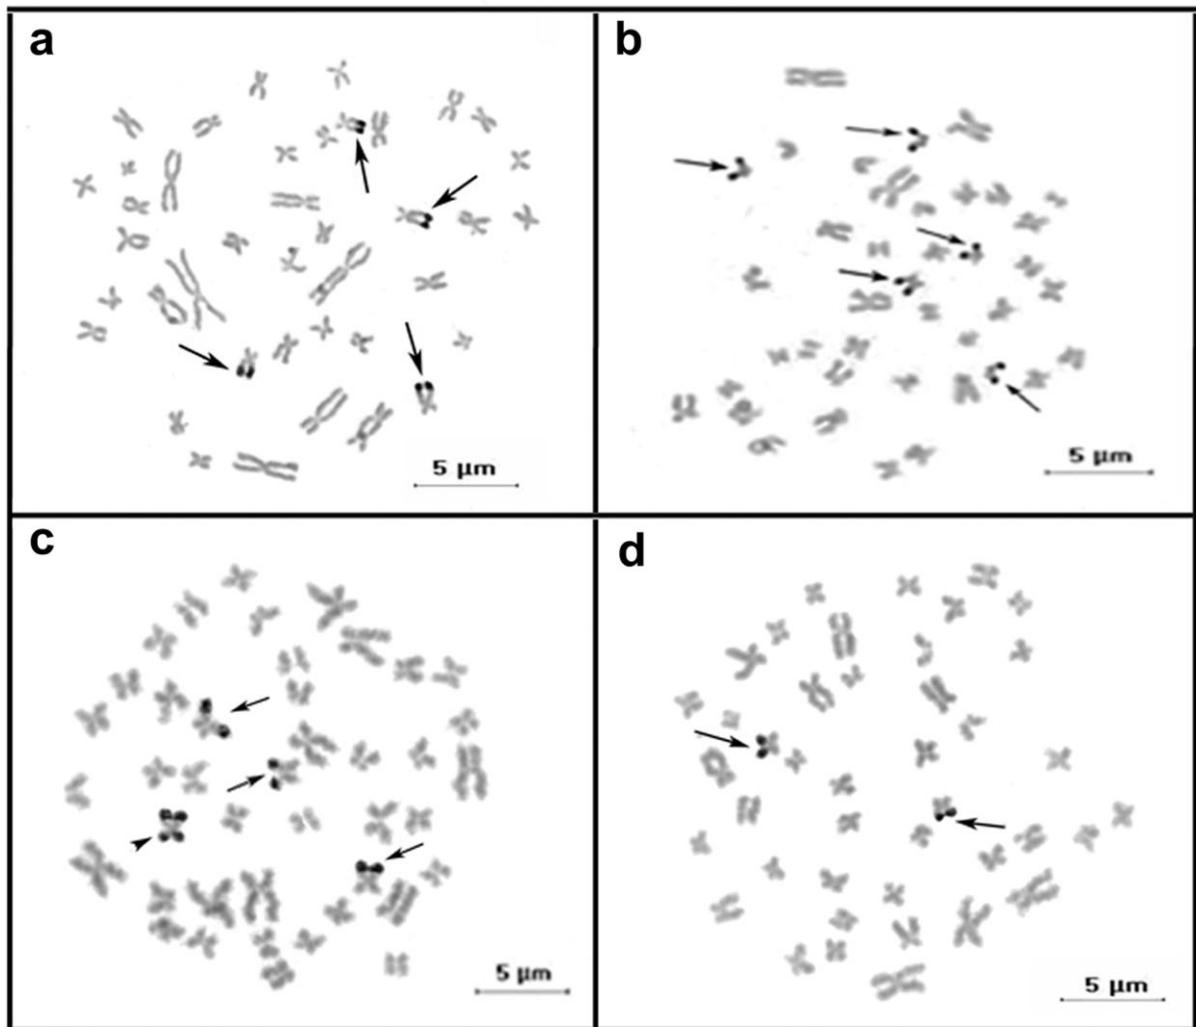

**FIG. 2.** Giemsa-stained and C-banded karyotypes of *Hoplias malabaricus*. (a) conventional Giemsa-stained karyotype of populations from Pandeiros and Pará rivers, (b) samples from Jacaré River and Tombadouro Creek, (c) C-banded karyotypes of males from Pará and Pandeiros rivers, (e) C-banded karyotypes of females from Pandeiros and Pará rivers, (d) C-banded karyotype of specimens from Tombadouro Creek; (f) C-banded karyotype from Grande River. Arrows indicate an interstitial heterochromatic block in the short arm of a homolog of the first chromosome pair. This block appeared in males of Pandeiros and Pará rivers populations, but not in females.

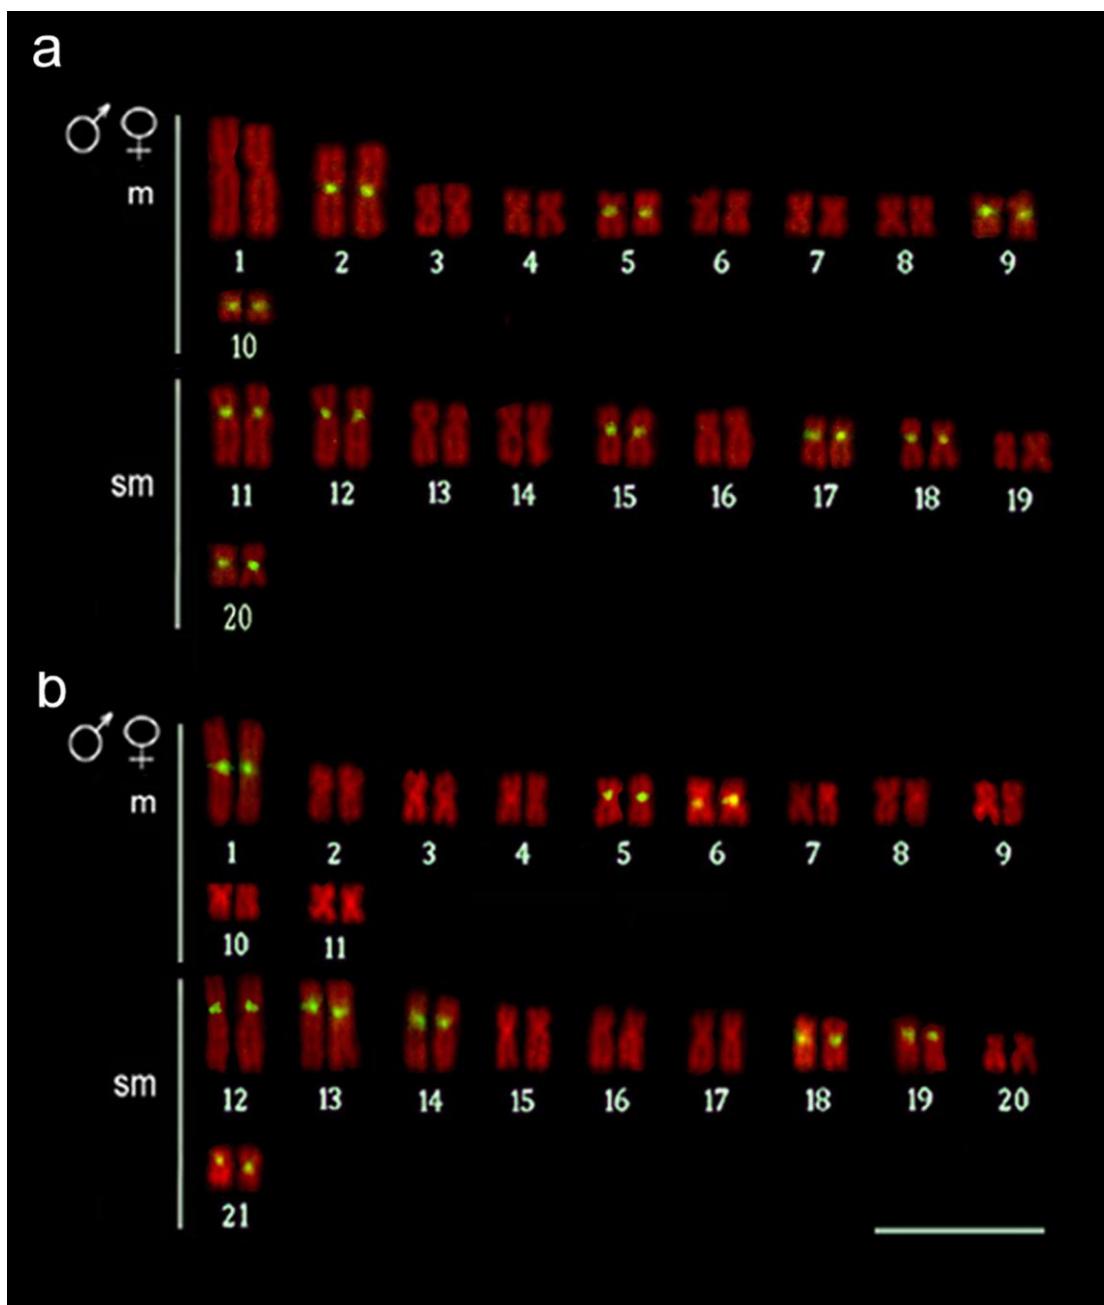

**FIG. 3.** Metaphase chromosome spreads of *Hoplias malabaricus* after FISH with 18S and 5S rDNA probes and DAPI/Chromomycin A3 staining. Numerical and positional variation of 18S rDNA sites in populations from (a) Pandeiros and Pará rivers, (b) Tombadouro Creek and Jacaré River. Mapping of 5S rDNA sites for populations of (c) Pandeiros and Pará rivers,

(d) Tombadouro Creek, and (e) Jacaré River. DAPI staining demonstrating absence of signals in males (f) and females (h) from Pará River. Arrow indicates the interstitial heterochromatic block negative for DAPI in one homologue of the first chromosome pair in males. Sequential CMA3 staining showing GC-rich DNA segments located on a submetacentric chromosome pair on (g) males and (i) females. Bar = 5  $\mu$ m.

**FIG. 4.** Metaphase chromosome spreads of *Hoplias malabaricus* after silver staining, showing Ag- NORs in populations from (a) Pará River, (b) Pandeiros River, (c) Tombadouro Creek and (d) Jacaré River. Arrows and arrowhead indicate telomeric and bitelomeric Ag-NORs, respectively.

**FIG. 5.** Karyotypes of *Hoplias malabaricus* samples from (a) Pará and Pandeiros rivers and (b) Tombadouro Creek and Jacaré River arranged from chromosomes probed with 5S *Hind*III-DNA counterstained with propidium iodide. Bar = 5  $\mu$ m.

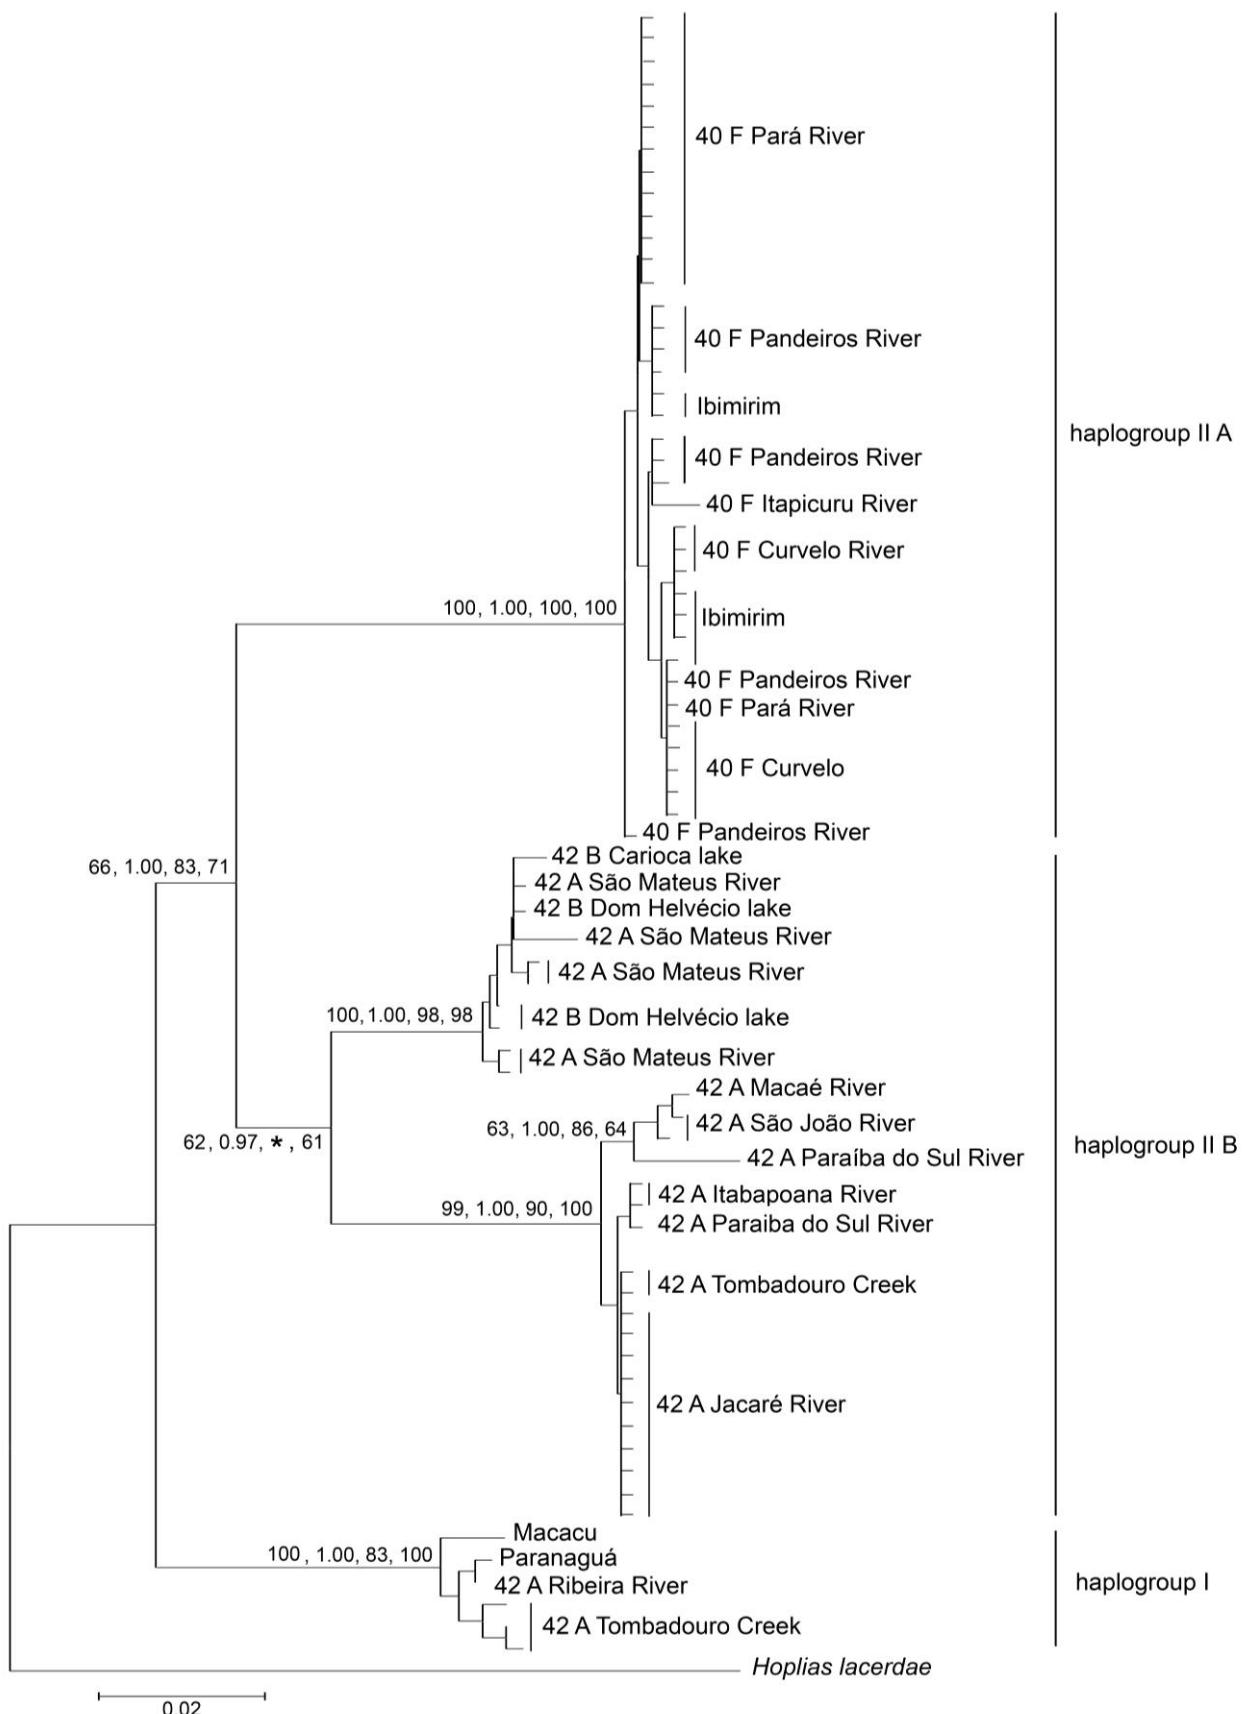

#### 4.2 MOLECULAR DATA

Multiple sequences 511 bp in length yielded 86 parsimony informative sites. Translation of these sequences into the corresponding amino acid

sequences resulted in 8 parsimony informative sites. The transitions:transversions ratio was 6.4, indicating that substitution rates were not saturated. The best model fit estimated with Modeltest and MrModeltest was HKY+G, which was used for NJ. In the tree, haplotypes were separated into 2 large clades with variable bootstrap support (Fig. 6). The largest bootstrap values were obtained for Haplogroup I, which was composed of the 2n=42A karyomorph from Tombadouro Creek, Ribeira, Paranaguá and Macacu rivers (Fig. 1). Haplogroup II was less supported and included all remaining trahiras ( $N = 67$ ), regardless of diploid number. Within this haplogroup, two subclades were highly supported: haplotypes derived from populations with the 2n=40F karyomorph (haplogroup IIA) and from populations with 2n=42A and 2n=42B karyomorphs (haplogroup IIB). Haplogroup IIA included all 2n=40 São Francisco trahiras, plus the Itapicuru River specimen. Haplogroup IIB included two well-defined lineages: one included haplotypes from the Doce and São Mateus rivers with no representatives in the Grande River, and a second lineage indicated a close phylogenetic relatedness between trahiras from the Jacaré (Grande River), the Tombadouro (São Francisco River) and the Macaé, São João, Itabapoana and Paraíba do Sul coastal basins. Within-haplogroup nucleotide molecular distances showed high levels of variation, with the smallest values in the São Francisco and Itapicuru samples and the largest in the IIB haplogroup. The range of between-haplogroup variation was much smaller (Table II).

Table II. Within- and between-haplogroup molecular distances in *Hoplias malabaricus*.

	Haplogroup I, 2n=42	Haplogroup IIA, 2n=40	Haplogroup IIB, 2n=42
Haplogroup I, 2n=42	0.032		
Haplogroup II A, 2n=40	6.82	0.0053	
Haplogroup II B, 2n=42	9.20	9.50	2.65

**FIG. 6.** Phylogenetic relationships of ATPase 6 haplotypes derived from *H. malabaricus* karyomorphs. The topology was obtained with neighbour joining

analysis. Statistical support are expressed as neighbour joining/Bayesian/maximum likelihood/maximum parsimony. The asterisk indicates a polytomy with ML analysis. Bar = molecular distance.

## 5. DISCUSSION

### 5.1 KARYOTYPIC DATA

#### *Karyomorph* $2n = 40F$

In addition to specimens from Tombadouro Creek, all samples from the São Francisco drainage shared the same karyomorphic formula, which is considered to be characteristic for São Francisco Basin populations (Bertollo *et al.*, 2000). The distributional pattern of heterochromatin was similar to that described by Dergam & Bertollo (1990) for the Três Marias population in this basin (Fig. 1), except for the presence of a heterochromatic block that was always restricted to one homologue of the first chromosome pair in males. This pattern suggested a probable XX/XY sex chromosome system in these populations, because this variant occurred only in males and was absent in females. This sex chromosome differentiation involving only heterochromatinization is a novelty within *H. malabaricus*, because all other sex chromosome systems described for this species complex involve translocations between chromosome pairs (for example, karyomorphs  $2n=39/40D$  and  $2n=40/41G$ ) (Bertollo *et al.*, 2000), or translocation and heterochromatinization, as proposed for the evolution of the  $2n=42B$  karyomorph from a  $2n=42A$  karyomorph ancestor (Born & Bertollo, 2000). The  $2n=40/41G$  karyomorph also has a large first pair of metacentrics and is therefore morphologically closest to the  $2n=40F$  karyomorph. Females with both karyomorphs have identical karyotypes and may be sister karyomorphs or species. Ongoing studies including these karyomorphs, using additional chromosomal markers will allow for a more thorough hypothesis of the evolutionary origins of this sex chromosome system.

C-positive heterochromatic bands were always located in the centromeric/pericentromeric region of all chromosomes and in the telomeric region of some pairs, in addition to multiple Ag- NORs sites. These heterochromatic and NOR characteristics were similar to those reported for other populations or karyomorphs of *H. malabaricus* (Dergam & Bertollo, 1990; Haaf *et al.*, 1993; Bertollo, 1996; Bertollo *et al.*, 1997; Born & Bertollo, 2000; Vicari *et al.*, 2003; Vicari *et al.*, 2005). In the Pandeiros River sample, Ag-NORs were restricted to telomeres of some chromosomes and appeared in larger numbers than 18S rDNA sites, but the latter also hybridized to the pericentromeric region of 1 chromosome pair (Fig. 3 a). There is currently no explanation for the apparently nonspecific nature of some telomeric Ag-NORs in the Pandeiros sample, which is as large as 7 in the Três Marias region (Dergam & Bertollo, 1990). On the other hand, pericentromeric 18S rDNA sites were not visualized by the silver nitrate method (these data and Dergam & Bertollo, 1990), which may be due to preferential telomeric NOR activation, as already pointed out for other trahiras' karyomorphs (Vicari *et al.*, 2005). Hybridization sites of the 5S rDNA probe were interstitially located in a small metacentric pair in both populations, a pattern also reported for trahira samples from Três Marias (Ferreira *et al.*, 2007). The patterns obtained with repetitive DNA class 5SHindIII-DNA were similar to those obtained for the Três Marias population (Ferreira *et al.*, 2007).

#### *Karyomorph 2n=42A*

The karyotypes of specimens from Tombadouro Creek and Jacaré River were characterized as karyomorph 2n=42A, a widespread karyotypic form in the Neotropics (Bertollo *et al.*, 2000). C-banding evidenced conspicuous centromeric blocks in almost all chromosomes, an overall pattern also reported by Born & Bertollo (2001) for other Grande River 2n=42A populations. High levels of Ag-NOR variation observed in the Tombadouro Creek population have also been reported elsewhere in the Grande River Basin (Born & Bertollo, 2001). Jacaré River trahiras showed Ag-NORs restricted to 1 chromosome pair, characterizing the lowest number of activated NORs reported so far as a fixed character state for any *H.*

*malabaricus* population. However, FISH with an 18S rDNA probe showed a larger number of NORs cistrons in both 2n=42A karyomorph populations.

On the other hand, FISH mapping with a 5S rDNA probe revealed differences between the Tombadouro Creek and the Jacaré River populations, where they hybridized on a large submetacentric and a small metacentric pair, respectively. This difference contrasted with previous reports of other trahira populations from the Upper Paraná Basin, the Araguá River, where both pairs showed fluorescence with this probe (Martins *et al.* 2006). Considering that at least some specimens from both basins shared identical haplotypes (see below), these population differences highlighted the great potential of this probe for population studies.

Patterns of variation of 18S rDNA were substantially different from the ones reported by Cioffi *et al.* (2009). These authors indicated the presence of five sites in the 2n=42B karyomorph and four fluorescent sites in a 2n=42A karyomorph from the Upper Paraná Basin, whereas the results of this study showed that the same karyomorph in the Jacaré and Tombadouro populations had three fluorescent sites. This reduction in numbers was also evident in the 2n=40F karyomorph, when compared to the 2n=40C and 2n=39/40D karyomorphs, which showed five fluorescent sites. Thus, this probe appears to be especially informative for studying among-karyomorph variation.

According to the haplotype-based trees, 5SHindIII-DNA patterns reflected a small increase in site numbers (from 18 to 20); Cioffi *et al.* (2009) also found variation in site numbers for other 2n=42 and 2n=40 populations. Also, the fluorescent centromeric region in the first or second chromosome pairs appears to be particularly informative. The presence of the fluorescent region in the first chromosome pair was observed in the 2n=42A karyomorph, as is the case for 2n=42B, 2n=40C and 2n=39/40D karyomorphs (Cioffi *et al.*, 2009), representing a plesiomorphic state. On the other hand, the 2n=40F karyomorph showed an apparently apomorphic condition, where the fluorescent region occurred in the second chromosome pair. Absence of the

fluorescent site in the first chromosome pair might be attributed to a more recent origin of the first chromosome pair and its possible origin from chromosomes lacking this site. However, this hypothesis involves a particularly complex evolutionary process, because the persistence of diploid number would also involve alterations of other chromosome pairs. Alternatively, the  $2n=40F$  karyomorph might have evolved directly from a  $2n=42A$  ancestor, causing a reduction in diploid number and producing an independent  $2n=40$  lineage. This hypothesis is consistent with the hypothesis of Bertollo *et al.* (2000), based on gross chromosome morphology, that the  $2n=40F$ ,  $2n=40/41G$  and  $2n=42E$  karyomorphs represent a monophyletic group within *H. malabaricus*.

In the submetacentric chromosome group, the pattern of fluorescent centromeric sites in three major chromosome pairs also sets apart the  $2n=40F$  karyomorph from other karyomorphs. The  $2n=42A$  karyomorph and the three karyomorphs reported by Cioffi *et al.* (2009) have conspicuous fluorescent centromeric regions in these pairs, while this number was reduced to two pairs in the  $2n=40F$  karyomorph. Homeologies among other chromosome pairs seem less reliable and must await further data. These FISH results and the presence of a unique sex chromosome system clearly indicate that the  $2n=40F$  karyomorph is a taxon with the largest suit of derived karyotypic characters in this species complex.

## 5.2 MOLECULAR DATA

Molecular data are congruent with the cytogenetic results and suggest a long reproductive isolation between the karyomorphs. Haplogroup I included some of the  $2n=42A$  karyomorph haplotypes from the Tombadouro Creek and haplotypes derived from three coastal basins located south of the Paraíba do Sul River. This haplogroup showed low levels of within variation, suggesting that these haplotypes were closely related. Some haplogroup II haplotypes were sympatric with haplogroup I haplotypes at the Tombadouro Creek. Within haplogroup IIB, all haplotypes from the Grande River were closely related to haplotypes from four coastal basins. These haplotypes

showed a sister group relationship with haplotypes from the São Mateus and Doce coastal basins that were not represented in samples from the São Francisco and Grande rivers. Some 2n=42 trahiras from the Tombadouro Creek and Jacaré River shared identical haplotypes, suggesting a recent range expansion from the Grande to the São Francisco basins.

These results provide insights into the evolution of *H. malabaricus* karyomorphs and the history of contact between coastal and continental hydrological basins. The most inclusive study of ND2 and ATPase 6 divergence between freshwater fishes is Bermingham *et al.* (1997), who estimated a rate of divergence for this gene segment of 1.3% per million years. Overall sequence (p-distance) divergence of the divergent haplogroup I haplotypes versus haplogroup II haplotypes would suggest a lineage split at 4.2 million years ago, an age that is younger than the inferred Amazon-Paranean vicariance, which has been dated at 11.8–10 million years ago (reviewed in Lundberg *et al.*, 1998). This isolation left 2n=42 and 2n=40 karyomorphs in both basins (Bertollo *et al.*, 2000), indicating that karyotypic evolution was well underway during Late Miocene Epoch. Miocene fossils are also considered to be similar to present-day taxa (Lundberg, 1998). The information content of molecular variation of this species complex may be more elusive: a preliminary analysis of ATPase 6 sequences in *H. malabaricus* populations from the Amazon-Paranean boundary basins reveals two clades that show large differences in p-distance divergence within each clade (0.10 and 0.34% per million years, respectively) (JAD, unpublished data), suggesting that molecular evolution within the *H. malabaricus* complex may be highly variable and influenced by other causes. Factors such as efficiency in DNA repair mechanism (Britten, 1986), generation time (Wu & Li, 1985), metabolic rate (Martin & Palumbi, 1993) and demographic processes (Ohta, 2002) may affect substitution rates among taxa. Hence, it is plausible to hypothesize a strong effect of demographic processes on the rates of molecular substitution in these populations, considering the close phylogenetic relationships among *H. malabaricus* karyomorphs and the adaptation of trahiras to life in small populations—which is also reflected in their high levels of karyotypical variation. Slightly

disadvantageous substitutions can drift to high frequencies in small populations (Ohta, 2002), thereby altering substitution rates in the DNA. Therefore, trahiras and other species with similar ecology may be particularly poor candidates for using the molecular clock hypothesis to estimate divergence times. In the highly migratory species, *Prochilodus* spp., substitution rates of ATPase 6,8 range from 0.8–2.5% (Sivasundar *et al.*, 2001), suggesting haplotypes in *H. malabaricus* are among the most divergent in the Neotropical region. The present study is the first to indicate such a deep molecular divergence within the same karyomorph, although deep cytochrome *b* divergences were also observed among populations of the catfish *Pimelodus albicans* in the River Plate Basin (Vergara *et al.*, 2008).

The location where lineage splitting occurred is limited to the distribution of current karyomorphs. The Paraná Basin harbours at least three karyomorphs, while the 2n=40F karyomorph appears to be widespread in the São Francisco Basin, and the 2n=42A karyomorph is apparently restricted to the Pará River headwaters. North-eastern coastal populations harbour the 2n=40F karyomorph as far as the Buranhém River to the south (JAD, unpubl.) (Fig. 1), and these haplotypes had the lowest degree of divergence. This macro-geographical pattern suggests that lineage splitting occurred elsewhere and not in the relatively isolated São Francisco Basin. In haplogroup IIB, the close relationship between the 2n=42A and 2n=42B karyomorphs indicated that karyotypical differentiation involved few alterations that resulted in a differentiated XX/XY chromosome system (Bertollo *et al.*, 2000).

### 5.3 STREAM PIRACY

On a local scale, the apparently restricted range of the Tombadouro Creek 2n=42A karyomorph may have resulted from stream piracy from a former Jacaré River tributary. The Tombadouro Creek is 12 km from the Jacaré across the Galga water Divisor. Three hypotheses might explain this dispersal. First, boundary crossing may have resulted from either human mediated activities. For example, the connection may have been destroyed

by the construction of BR 494 Highway, which is 8 km away at its closest point from the Tombadouro Creek. Second, dispersal may have occurred through a high-altitude wetland that used to drain into both basins. Third, headwater capture in the region may have occurred by relatively recent reactivation of ancient faults (Saadi *et al.*, 2002). Altitudinal characteristics are also consistent with the direction of stream capture. Tombadouro is at 860 m altitude, whereas the Jacaré River is at 1038 m. This area is within the range of a continental fault known as the Upper Grande River Crustal Discontinuity (Saadi *et al.*, 2002). This fault represents the southern limit of the São Francisco craton and the movable belts of southern Minas Gerais State (Fig. 1) and has been active in the last 15 000 years.

The phylogenetic origins of two highly divergent haplotypes in the Tombadouro Creek became clear only after haplotypes from coastal basins were included in the analysis. Most critically, haplotypes found in sympatry in the São Francisco River are related to haplotypes in different coastal basins. Under the allopatric model of speciation, this asymmetry suggests that ancestral fish dispersed from the coastal to the continental drainages, and the present study is the first to indicate unambiguously the direction of this dispersal. However, the timing of the dispersal between coastal and inland drainages could not be estimated, because molecular clock expectations are not suitable for trahiras. Therefore, the phylogeographic history this group does not fit any of the three phylogenetic patterns proposed by Ribeiro (2006). On the other hand, low genetic divergence between the São Francisco and Itapicuru drainages may be part of a recent faunal exchange in the arid region of north-eastern Brazil that is apparent in many other species of fish (Rosa *et al.*, 2004).

Ribeiro (2006) indicated that the Atlantic drainages (Doce, Paraíba do Sul and Ribeira) have existed since the breakup of Gondwana. The results of the present study suggested that populations in these basins represent three biogeographic units, for which only two have close representatives in the boundaries of the Jacaré and Pará drainages. Dergam *et al.* (2002) previously reported a close phylogenetic relatedness between two

haplotypes in the Doce and lower Grande river basins. Fish dispersal from coastal to continental drainages may have been restricted to only a few taxa adapted to headwater conditions, because coastal drainages are characterized by high levels of endemism (Ribeiro, 2006) and the Proterozoic Mantiqueira Range is considered to be an efficient barrier between coastal and continental drainages (Ingenito & Buckup, 2007). To the south, stream piracy has been particularly intensive in the Paraíba do Sul, Ribeira and Upper Paraná basins (Ribeiro, 2006).

The present study provided important information on the population distribution of *H. malabaricus* in São Francisco Basin and on historical relationships with populations in the Grande and coastal basins. The  $2n=40F$  karyomorph and its associated haplotypes were widely distributed throughout the São Francisco Basin, maintaining an apparently stable karyotypic structure of the chromosomal markers analyzed here. This karyomorph was characterized by a XX/XY sex chromosome system. In contrast, the  $2n=42A$  karyomorph showed a more restricted distribution in São Francisco Basin and was closely associated with populations in a Grande River Basin tributary, where the  $2n=42A$  karyomorph predominated. However, the  $2n=42A$  karyomorph populations isolated in drainages showed striking differences for some markers, notably the Ag-NORs and 5S rDNA sites. The patterns of variation in repetitive DNA sequences as revealed by 5S rDNA probes indicated that these markers appeared to be useful population markers, showing significant differences among localities and karyomorphs. Patterns of 5SHindIII-DNA variation yielded the largest phylogenetic signal and placed the  $2n=40F$  karyomorph in a high position in the phylogeny of karyomorphs that occur in eastern Brazil.

Given the current status of phylogenetic data, an understanding of distribution patterns for *H. malabaricus* will be particularly challenging. Studies of the distribution patterns of freshwater fishes have considered endemism (e.g. Vari, 1988), faunal composition including endemic and widespread species (Hubert & Renno, 2006), molecular data (Sivasundar et al., 2001; Montoya-Burgos, 2003) or a combination of morphological and

molecular data (Menezes *et al.*, 2008). When integrated into a wider geographic context, molecular and cytogenetic patterns can be informative of faunal dispersals between drainages. The results of the present study suggested that recent fish dispersal may occur even within apparently stable geological regions and that headwater stream piracy between coastal and continental (Upper Paraná tributaries) basins may have played a role in producing the high levels of freshwater fish diversity in the Neotropics.

Finally, the topology of mtDNA-based tree suggests that the proposal of Dergam & Bertollo (1990) to separate species by diploid numbers would result in a paraphyletic arrangement, in which some trahiras haplotypes associated with  $2n=42$  karyomorphs would be more closely related to trahiras with  $2n=40$  karyomorphs than to other fish with  $2n=42$  karyomorphs. Although haplogroup I appeared as the sister group of the remaining trahiras, haplogroup II is less supported and the possible ancestry of karyomorphs must wait for more data. A time frame for dispersal between coastal and continental drainages is elusive for the *H. malabaricus* species complex. Nevertheless, geographical isolation during coastal diversification has enhanced speciation processes and genetic isolation between karyomorphs, a process that has resulted in molecular and cytogenetic differentiation between populations. These results are consistent with the existence of multiple independent lineages that can be easily detected with standard cytogenetic techniques.

Although trahiras are common members of lowland freshwater communities (Bonetto *et al.*, 1969; Winemiller, 1991), at least part of their widespread distribution in the Neotropics is due to their ability to dwell in high-altitude headwaters, such as in the Jacaré and Tombadouro localities. The question of how this nonmigratory sedentary species has adapted to sluggish waters and to waters in high altitudes is not explained by current geological data. Nevertheless, this broad ecological diversity indicates a long history of trahiras in south-eastern Brazil.

José Tiago da Costa, João Batista Santos, Sr. Raul de F. Guimarães and Anderson M. R. de Souza provided support during fieldwork. Walter Evangelista and Uedson Jacobina collected samples from the Ibimirim lakes and Itapicuru River, and Tiago Leão Pereira assisted with some lab work. Milena Wachlevski supported the initial stage of this study. The authors wish to thank two anonymous reviewers for their suggestions. Financial support for this study was provided by the Program for the Advancement of Research of the Universidade do Estado de Minas Gerais, the National Council for Technological and Scientific Development of the Brazilian Government, the Universidade Federal de Viçosa and the Fundação Educacional de Divinópolis-FUNEDI/UEMG.
